A STUDY OF FLOW CONDITIONS
IN SHAFT SPILLWAYS

Approved:

M. A. Cantow
Chairman
J. E. Kindervat
Nelson C. Ward

Date approved by Chairman: 12/18/69

In presenting the dissertation as a partial fulfillment of the requirements for an advanced degree from the Georgia Institute of Technology, I agree that the Library of the Institute shall make it available for inspection and circulation in accordance with its regulations governing materials of this type. I agree that permission to copy from, or to publish from, this dissertation may be granted by the professor under whose direction it was written, or, in his absence, by the Dean of the Graduate Division when such copying or publication is solely for scholarly purposes and does not involve potential financial gain. It is understood that any copying from, or publication of, this dissertation which involves potential financial gain will not be allowed without written permission.

August G. Mussalli

ACKNOWLEDGMENTS

The author would like to express his sincere appreciation and thanks to Dr. M. R. Carstens for his valuable guidance, criticism, and patience throughout the duration of the study. Dr. Carstens suggested the problem, supervised the investigation, and served as the chairman of the thesis reading committee. The other members of the reading committee were Regents' Professor Carl E. Kindsvater and Dr. Henderson C. Ward. Special thanks are due Mr. Homer J. Bates, Principal Laboratory Mechanic, whose help in carrying out the experimental program was invaluable. Thanks are also due Mr. Benjamin T. Hendricks, Photographer; Miss Ruth Hale, Interlibrary Services Librarian; Miss Janet Sloboda, Library Assistant; and Mrs. Susan Coggins, Report Typist, of the Georgia Institute of Technology staff. Appreciation is extended to Mr. Stephen H. Poe, Chief, Technical and Foreign Services Branch, U.S. Bureau of Reclamation and to Mr. Manuel Rocha, Director, Laboratório Nacional de Engenharia Civil, Portugal for supplying data on existing shaft spillways; to Professor Osman N. Çatakli, Professor of Hydraulic Structures, Technical University of Istanbul; Mr. P. A. Banks; Mr. E. P. Fortson, Jr., Chief, Hydraulics Division, Waterway Experiment Station, U.S. Army Corps of Engineers; and to Mr. Harold W. Humphreys, Head, Hydraulic System Section, Illinois State Water Survey, for sending literature on shaft spillways and related subjects.

Gratitude for financial support is expressed to the Office of

Water Resources Research, Department of the Interior, through project B-022-GA, and to the School of Civil Engineering, Georgia Institute of Technology.

Permission has been granted by the Graduate Division for special pagination and margin widths in order to enable this dissertation to be published as a report of the Water Resources Center, Georgia Institute of Technology.

than 2.0 are recommended, since bends of larger ratios of r/D_b generate less waves.

A general discussion on shaft spillways is presented covering: vertical versus inclined shaft spillways, free versus submerged inlet, partly-full versus full conduit, conduit-size determination, bend curvature, and air demand. Design examples are also presented.

The results of this study are not aimed to eliminate the need of model studies but rather to enable the designer to make better initial designs.

Figure 2. Elements of a Vertical Shaft Spillway

types of inlet crests, the standard crest and the flat crest as shown in Figures 3a and 3b.

The vertical transition between the inlet crest and the vertical shaft is formed in the shape of an aerated lower nappe of a flow over a sharp-crested circular weir. The junction between the transition and the vertical shaft is the throat of the transition. This type of spillway inlet structure is often called a "morning glory", "glory hole", or "bellmouth" spillway.

The vertical shaft cross section is designed to accommodate the design flow and is made with a constant diameter for ease of construction.

The vertical bend connects the vertical shaft to the horizontal leg of the spillway. The bend is usually a simple circular bend. The curvature of the bend is chosen so as to facilitate the passage of timber logs and bulky debris which inadvertently might enter the spillway.

The horizontal leg of the spillway is usually a part of the diversion tunnel which diverts the river water while constructing the dam. The horizontal conduit is designed to flow either full or partly full throughout the discharge range because the transition from open-channel flow to pipe flow is accompanied by surging of the flow which results in undesirable vibrations.

The outlet structure is usually either a flip bucket or a sloping apron with a conventional stilling basin. The flip-bucket outlet directs the high velocity water into the air where much of the excess energy is dissipated prior to falling back into the river. In a conventional stilling basin, the excess energy is dissipated by turbulence generated in a hydraulic jump.

Auxiliary structural elements are added to a shaft spillway to improve the flow conditions if needed. The inlet can be gated as shown in Figures 3c and 3d to control the pool elevation. Anti-vortex arrangements such as piers over the inlet crest (Figure 3e), fins along the crest profile (Figure 3f), or a curtain wall across the inlet (Figure 3g) are added to break vortex action which decreases the discharge capacity and which can cause increased wave action further down the conduit. A deflector can be added at the inner wall of the throat (Figure 4b), at the crown of the bend (Figure 4d), or at the roof of the upstream end of the horizontal conduit (Figure 4e) to suppress wave action further along the axis of the conduit. Air vents can be added at the throat of the shaft (Figure 4b), along the inclined or vertical shaft (Figure 4c), below the deflector at the crown of the bend (Figure 4d), after the deflector at the upstream end of the horizontal conduit (Figure 4e), or along the roof of the horizontal conduit (Figure 4f) to relieve negative pressures and to aerate the flow.

3. Discharge Characteristics of a Shaft Spillway

Typical flow conditions and discharge characteristics of a shaft spillway are shown on Figure 5.

For small heads over the inlet weir crest the discharge is weir flow with,

$$Q \propto |H|^{1.5}$$

in which Q is the discharge and H is the total head over the spillway crest. The vertical transition beyond the crest flows partly full. The flow clings to the sides of the shaft as shown in Figure 5a. Air is

Figure 4. Aeration of a Shaft Spillway

diameter of the falling water jet at that section such as by inserting a deflector as shown in Figure 6c, tends to fill the shaft with water before the flow is controlled at the throat, with the result that the flow control shifts directly from weir to short-tube.

Proportioning of the size of the horizontal conduit to the size of the vertical shaft changes the ordinates of the points of transition of the flow controls. If the size of the horizontal conduit is equal to that of the vertical shaft as shown in Figure 6d, the transition from weir to pipe control or from short-tube to pipe control occurs when the flow fills the horizontal conduit thus shifting the control to the outlet portal of the conduit. If the size of the horizontal conduit is greater than the size of the vertical shaft as in Figure 6e, the transition from weir to pipe control or from short-tube to pipe control might not occur, that is, the horizontal conduit flows partly full. If the size of the horizontal conduit is smaller than the size of the vertical shaft as shown in Figure 6f, the flow fills the horizontal conduit while the vertical shaft is flowing partly full with the result that the control shifts from weir to pipe.

The type of flow control desired depends on the purpose of the spillway. If the purpose is to pass excess flood water without overtopping the dam, the spillway will be designed to discharge freely with weir control throughout the discharge range. If the purpose is flood control where the discharge is to be limited in the river downstream from the dam, the spillway crest will be designed to operate unsubmerged with lower discharges and to operate submerged with higher discharges.

4. Why a Shaft Spillway?

Shaft spillways provide a practical solution for spillways at earth and rockfill dams and at dam sites in narrow canyons where the abutments rise steeply.

A masonry or concrete dam combined with a spillway is no longer the standard solution for impounding water in a reservoir. Earth and rockfill dams are being used more frequently for this purpose. For reasons of safety and also of economy of construction, a spillway located away from the dam often provides the best solution.

At narrow dam sites, in a conventional concrete dam, the space is too limited to accommodate a straight overflow spillway. The necessary length of crest can be obtained with the circular weir inlet of the shaft spillway. In thin arch dams spillway openings over or through the dam present vibration problems. Difficulties are also experienced in hanging gates and control gear on such slender structures. Thus, the alternative of a spillway located away from the dam is a practical solution.

In all these situations the excess flood water can be carried around the dam by means of a shaft spillway. In case a diversion tunnel was already excavated to conduct the river around the site during construction, this diversion tunnel can also be used as the horizontal leg of the spillway as shown in Figure 1a. Thus, only the vertical shaft is needed to be excavated. With improved tunneling techniques the driving of shafts and tunnels can be carried out both rapidly and economically.

Hydraulically, the shaft spillway can be operated to fulfill the purpose of the dam. If the purpose is passing excess water, then

the shaft spillway is designed to discharge freely with weir control with the result that near maximum capacity is attained at relatively low heads. If the purpose is flood control, then the shaft spillway is designed to discharge submerged.

B. Description of the Problem

The fact that shaft spillways are a small percentage of spillways for large dams is due, apart from considerations of suitability of site, to undesirable characteristics of shaft spillways as compared to unroofed spillways. The undesirable characteristics are: (1) submergence of the inlet, (2) increased possibilities for vibration, and (3) clogging of the spillway.

1. Submergence

The inlet of a shaft spillway submerges at a definite value of the ratio of the head over the crest to the diameter of the crest, H/D_{cr} . After submergence, little increase in discharge is gained with the rise of head over the crest as shown in Figure 5e. Submergence limits the effectiveness of the shaft spillway should the design discharge be exceeded, which would endanger the dam, especially an earth dam. To overcome this shortcoming, an emergency or auxiliary spillway can be incorporated to operate when the spillway design discharge is exceeded. Otherwise, the shaft spillway must be designed to operate unsubmerged with discharges resulting from the maximum probable flood.

2. Increased Possibilities for Vibration

Vibrations in a shaft spillway may be initiated (a) by a shift of the flow control and (b) by blow back of entrapped air pockets.

a. Shift of Flow Control. Unstable flow conditions occur when the flow control shifts resulting in vibration of the structure. In a shaft spillway a shift of control can occur from weir to orifice control, from weir to short-tube control, from orifice to short-tube control, from short-tube to pipe control, and from weir to pipe control as shown in Figure 7.

(1) Weir to Orifice and Weir to Short-tube Control. If the profile of the transition between the crest and the vertical shaft is steeper than the profile of a lower nappe of an aerated flow over a sharp-crested circular weir, negative pressure develops in the air pockets underneath the lower nappe of the flow. Pressure fluctuations occur as intermittent amounts of air flow from the outlet to the air pockets. Pressure fluctuations can cause vibrations of the structure. As the water discharge increases, the water fills the shaft decreasing the possibility of air flow to the entrapped air pockets. The negative pressure in the air pockets sucks more water discharge and the shaft fills completely with water removing all the entrapped air. The flow control shifts from weir to orifice or from weir to short-tube with the reservoir surface elevation remaining the same as shown in Figure 7a. The sudden increase of discharge causes an abrupt increase in the dynamic load on the structure. Pressure fluctuations and the sudden shift of control can be eliminated by shaping the transition profile like that of a lower nappe of an aerated flow over a circular sharp-crested weir or by maintaining atmospheric pressure through ventilation.

(2) Orifice to Short-tube Control. If the diameter of the vertical shaft is larger than the diameter of the falling water jet

Figure 8. Pressure Fluctuations in the Horizontal Conduit

As the water waves touch the roof of the conduit, the conduit seals resulting in pressure fluctuations along the horizontal conduit as shown in Figure 8b and in a shift to pipe control accompanied by an increase in water discharge. As the waves "untouch" the roof, a shift back to weir control takes place accompanied by a decrease in water discharge. The reservoir pool elevation remains the same as the water discharge varies. The shift of controls is undesirable because the shift causes vibrations in the structure and variation in the water discharge. Sealing and the subsequent vibrations can be eliminated by maintaining atmospheric pressure along the conduit, by choosing a suitable bend curvature, and by allotting more conduit area than needed for the water flow to allow for the waves and still maintain partly-full flow.

In laboratory hydraulic model studies of shaft spillways, where the reservoir pool is very small, a cyclic shift of controls occurs. The pool elevation fluctuates and the water discharge varies with the shift of control. Figure 9 shows the surging occurring with a flow through a vertical pipe. Figure 10 shows the flow characteristics of the cyclic shift of controls which can occur in hydraulic models of shaft spillways with weir control (Figure 10a) and with short-tube control (Figure 10b). The cyclic shift of controls is accompanied by vibration of the spillway model.

Swaying motion in the horizontal conduit, caused by asymmetric flow entrance conditions at the inlet, can lead to sealing of the conduit and vibration of the structure. The supercritical flow in the circular horizontal conduit appears to slosh back and forth along the conduit. This wave action tends to hasten transition to pipe control.

Figure 11. Blow Back and Blow Out of an Entrapped Air Pocket

spillway was completed in England in 1896. However, the design did not come into general use until the latter part of the 1920's. Since then many shaft spillways have been constructed all over the world. A list of some spillways is given in Table A-1 of Appendix A.

1. General

Several investigators have written about the design of shaft spillways. In 1925, Kurtz 1/ was the first to give a comprehensive discussion of a shaft spillway. Discussion by several prominent engineers 2/ added materially to Kurtz's paper. In 1937, Binnie 3/ gave comprehensive descriptions of seven shaft spillways and the results of model studies. In 1945, Creager, Justin, and Hinds 4/ presented design methods for shaft spillways. In 1956, the American Society of Civil Engineers published a symposium on morning-glory spillways 5,6,7/ in which 18 shaft spillways were described and their operating characteristics discussed. Abecasis 8/ supplemented the ASCE symposium with the description and operating characteristics of three Portugese shaft spillways. In 1958, Blaisdell 9,10,11/ reported model and field tests on closed-conduit spillways used in soil conservation projects. In 1960, the U.S. Bureau of Reclamation (U.S.B.R.) 12/ and in 1955, the Portugese National Civil Engineering Laboratory (L.N.E.C.) 13/ presented comprehensive information for the design of shaft spillways.

2. Design Information

From model studies and prototype observations, design information for the various elements of a shaft spillway have been developed.

a. Inlet. The inlet crest profile is shaped as of an aerated lower nappe over a sharp-crested circular weir. Gourley 14/, Du Pont 15/,

and the horizontal conduit are ordinarily made of constant diameter. However, no section of the vertical transition or of the vertical shaft should be smaller than that determined by Equation 1. The section at which the constant-diameter shaft intersects the profile determined by Equation 1 forms the throat of the shaft and has the minimum size that can accommodate the flow. Downstream from the throat section the shaft will have an excess of area.

c. Vertical Bend. The vertical bend is usually a 90° - circular bend. Taylor and Elsdon 28/ suggested a circular bend whose cross-sectional area increases over the first part of the bend and subsequently decreases. The U.S.B.R. in a standard reference book 12/ suggested:

Precautions must be taken, however, in selecting vertical or horizontal curvature of the conduit profile and alinement to prevent sealing along some portion by surging or wave action.

The U.S. Bureau of Reclamation used vertical bends of a ratio of the radius of curvature along the centerline to the bend diameter, r/D_b , ranging from 1.04 to 5.5 and the Portugese National Civil Engineering Laboratory used bend curvatures, r/D_b , ranging from 1.2 to 3.2. Bend curvatures used by designers over the world ranged from 0.5 to 5.5 as shown in Table A-3 of Appendix A. As a conclusion, there is no specific design criterion for the curvature of the vertical bend.

d. Horizontal Conduit. The horizontal conduit is designed to flow partly full at all discharges. However, some designers allow the conduit to seal at an intermediate discharge or design the horizontal conduit to flow full throughout the discharge range.

CHAPTER II

EXPERIMENTAL APPARATUS

A. Objective

The objective of the laboratory experiments was to study the phenomenon of sealing, which is the transition from free-surface flow to pipe flow in the horizontal conduit of a vertical-shaft spillway. Sealing with short-tube and with weir control were investigated. The geometric and flow factors affecting sealing were varied systematically. The geometric variables were the bend curvature, r/B , and the deflector. The flow variable was the air concentration in the water flow, Q_a/Q . The Froude number, F , of the free-surface flow in the horizontal conduit and the ratio of the area of the water flow to the conduit area, A/A_c , were determined experimentally throughout the discharge range until incipient sealing. The effect of the above mentioned factors on the pool elevation-discharge relation of a spillway was not evaluated.

In order to study the flow conditions of the free-surface flow in the horizontal conduit with weir-flow control over a range of Froude numbers, F , the water discharge, Q , and the water velocity, V , had to be controlled independently. This control was achieved by variation of the number of water jets which discharged from the supply line down into the vertical shaft.

B. Experimental Apparatus

The experimental measurements were made in a transparent enclosed

Figure 12. General View of the Vertical-Shaft Spillway Model

Figure 13. Diagram of the Vertical-Shaft Spillway Model

Figure 17. Diagram of the Multiple-Tube Outlet

brass plate was bolted to the flange of the 12-inch pipe above and connected to the reducer below by 0.5-inch diameter rods. The plate could be moved downward with the aid of sprockets welded over four of the bolting nuts and a chain as shown in Figure 15 in order to change the number of the rubber stoppers.

The vertical shaft could be varied in length from 4 to 14 inches as needed. For short-tube flow the 4-inch-long shaft was used and to simulate weir flow the 14-inch-long shaft was used. Deflectors of thickness of $t = 0.00, 1/16, 1/4$ and $1/2$ inches were inserted at the inner wall of the vertical shaft at the crown of the bend to deflect the flow away from the roof of the horizontal conduit and to enable free-surface flow conditions to prevail.

The bend section connected the vertical shaft to the horizontal conduit. Three 90-degree circular bends with $r/B = 0.5, 1.5,$ and 2.5 were tested.

The horizontal conduit was the main testing section where the phenomenon of the transition from free-surface to pipe flow, or seeping, occurred. The conduit was 4-inch square in cross section. A 4.2-foot-long conduit was used with short-tube flow control and a 6.2-foot-long conduit was used with weir-flow control. The horizontal conduit was equipped with 7 floor piezometers, $1/16$ -inch in diameter, as shown in Figure 18, placed 6-inches apart and one movable stagnation tube made of a hypodermic needle 0.025-inch in outer diameter and 0.020-inch in inner diameter. The tip of the stagnation tube was in the same cross section as the downstream floor piezometer. The piezometers and the stagnation tube were connected to an open-column manometer. At the

Figure 18. The Horizontal Conduit with the Piezometric Openings, Stagnation Tube, and Manometer

Figure 19. The Pressure Transducer and the Air Vents on the Roof of the Conduit

roof of the horizontal conduit five 1/4-inch air vents were installed in a row across the conduit roof. The row of vents was located one inch from the upstream end of the horizontal conduit as shown in Figure 19. A short piece of rubber tubing was attached to each vent so that each vent could be opened or closed by pinch clamps in order to admit air from the atmosphere to the conduit. A deflector 1-inch thick and 6-inches long was inserted on the roof at the upstream end of the conduit to study the deflector effect on sealing. A Pace pressure transducer was placed on the roof 5 inches from the upstream end of the conduit. The transducer was mounted on a 3-inch-long metal tube as shown in Figure 19. The Pace pressure transducer model KP15 is a diaphragm type in which the pressure is sensed through the deflection of a flat magnetic stainless diaphragm located between two magnetic pickup coil assemblies. Motion of the diaphragm results in a change in the inductance ratio between the pickup coils to produce an output voltage proportional to the pressure. The output signals from the pressure transducer were amplified and recorded on a two-channel Sanborn writing oscillograph model 60-1300. The oscillograph unit is shown in Figure 20. The pressure transducer could be connected to a water manometer, shown in Figure 21, for calibration of the transducer during each run.

2. Air Supply

Air discharge, Q_a , was a variable in the experiments. The air was supplied by an air blower. The air passed through a series of pipes, nozzle, and rubber hose (Figure 22), entered the enclosed spillway model downstream of the multiple-tube outlet, and mixed with the water in the reducer section as shown in Figure 16.

Figure 20. The Two-Channel Sanborn Writing Oscillograph

Figure 21. The Water Manometer for the Calibration of the Transducers

Figure 22. The Air Measuring Instruments Showing the Air Nozzle and the Differential-Pressure Transducer

A straight 3-foot-long 4-inch-diameter copper pipe was connected to the air blower and was followed by an aluminum smooth nozzle for air discharge measurement. The throat diameter of the nozzle was 0.755 inches. Piezometers at the upstream end and throat sections of the nozzle were connected to a Sanborn differential pressure transducer model 266B as shown on Figure 22. The transducer was of a diaphragm type and was connected to a two-channel Sanborn direct writing oscillograph through an amplifier. The transducer could also be connected to the water manometer, shown in Figure 21, for calibration of the transducer during a run. A 1-foot-long copper pipe followed by three 12.5-foot-long 1-inch-diameter rubber hoses connected the nozzle to the enclosed spillway model. Pinch clamps on the rubber hoses controlled the amount of air discharge admitted to the spillway. The air entered the spillway model through three air vents 1-inch in diameter drilled into the sheet metal, which was inserted in the 4-inch gap between the 12-inch water supply pipe and the reducer around the multiple-tube outlet as shown in Figure 16. Silastic rubber adhesive was used to seal the small spaces between the sheet metal and the flanges of the 12-inch pipe above and the reducer below to make the enclosed spillway model air tight.

CHAPTER III

EXPERIMENTAL PROCEDURE

The experimental investigation consisted of the study of the factors affecting the transition from short-tube to pipe control and the transition from weir to pipe control. The transition from free-surface flow to pipe flow in the horizontal conduit is called sealing. An experimental run consisted of setting up a combination of variables, calibration of instruments, and measurement of the flow characteristics and observation of the flow conditions.

A. Setup of a Run

The geometric and flow factors were varied systematically in order to evaluate the effect of each variable on the flow conditions in the horizontal conduit and on the phenomenon of sealing. The systematic setup of the variables at short-tube and at weir control follows.

1. Short-tube Control

a. Bend. Bends of $r/B = 0.5, 1.5, \text{ and } 2.5$ were tested. No deflector was inserted at the crown of the bend nor was air entrained into the water.

b. Deflector. Deflectors of thickness $t = 1/16$ inch, $1/4$ inch, and $1/2$ inch were inserted at the crown of the bend and a deflector of thickness $t = 1$ inch was inserted on the roof at the upstream end of the horizontal conduit. The deflectors at the crown of the bend were inserted in combination of each bend while the deflector at the upstream

end of the horizontal conduit was inserted downstream of the bend of $r/B = 1.5$ only.

c. Air. Various amounts of air were entrained into the water. An air discharge was entrained with each combination of bend and deflector.

2. Weir Control

a. Number of Water Jets. The number of jets discharging into the vertical shaft was varied to simulate the effect of crest-weir control on the water velocity in the horizontal conduit.

b. Air. Various amounts of air were entrained into the water to simulate the effect of aeration from the reservoir pool surface.

c. Bend. Bends of $r/B = 0.5, 1.5,$ and 2.5 were tested with each combination of air concentration and number of water jets. No deflector was inserted.

d. Deflector. A deflector of thickness $t = 1/2$ inch was inserted at the crown of the bend in combination of each bend, air concentration, and number of water jets. A deflector of thickness $t = 1$ inch was inserted at the upstream end of the horizontal conduit in combination with the bend of $r/B = 1.5$ only.

B. Calibration of Instruments

Prior to and after each experimental run, the pressure transducers on the horizontal conduit and at the air nozzle were calibrated. The connection arrangements of the pressure transducers to the water manometer and to the oscillograph are shown in Figure 23. Negative pressures were applied to both transducers by changing the water level

Figure 23. The Connections of the Transducers

in the manometer. Calibration traces were then recorded on the oscillograph chart together with the corresponding manometer deflections. A typical calibration curve is shown in Figure 24.

C. Measurement Procedure

During a run the following experimental procedure was followed. The control valve on the water supply line was opened. The deflections of the differential water manometer connected to the bend meter in the water-supply line were determined and recorded. A reading of the piezometer heads of the stagnation tube, situated at approximately 0.6 the depth of non-aerated flow and just in the clear water section in aerated flow, and of the static piezometer on the floor of the conduit were determined on the open-column water manometer and recorded. For non-aerated flow the depths of water flow at the section of the stagnation tube was measured by means of a scale and recorded. Pressure records of the conduit transducer and of the air transducer were traced on the oscillograph chart. The control valve was opened further in many steps covering all the water discharge range of the free-surface flow in the horizontal conduit till transition to pipe flow, or sealing, occurred. At incipient-sealing and at sealing conditions the piezometric heads along the horizontal conduit were determined.

Incipient-sealing and sealing conditions were determined more than once as a check. Supplementary runs were made with the air vents on the roof of the conduit open to evaluate the vent effect on sealing.

Sealing was decided upon with the aid of visual observation of the pressure record on the roof of the horizontal conduit, and of the

Figure 24. Typical Calibration Curves of the Transducers

piezometric-pressure readings along the floor of the conduit. Sealing occurs when the pressure on the roof as recorded by the oscillograph becomes positive and when the piezometric-head elevation at any section along the conduit is above the elevation of the roof of the conduit. A typical pressure record and piezometric-head elevations along the floor of the conduit at incipient-sealing and at sealing conditions are shown in Figure 25.

CHAPTER IV

ANALYSIS OF EXPERIMENTAL RESULTS

In this chapter the experimental results are presented and analyzed. Experimental data from other model studies and data of existing shaft spillways are also analyzed to verify the results of this experimental investigation. The flow conditions at weir and at short-tube control and the transition from weir to orifice control, from short-tube to pipe control, and from weir to pipe control are discussed.

A. Transition from Weir to Orifice Control

Inasmuch as this experimental investigation did not include the study of the transition from weir to orifice control, data obtained from other model studies are analyzed and presented.

1. General

If the purpose of a dam is flood control, irrigation, or public or industrial water supply, where the discharge is to be limited in the river downstream from the dam, the shaft spillway is designed to operate submerged at higher discharges. Submergence can be achieved by transition to orifice control as shown in Figures 5b and 6b. Of the ninety-six shaft spillways reviewed in Table A-3 of Appendix A, seventeen vertical-shaft spillways operated submerged at design capacity.

The discharge equation for weir control is:

$$Q = C D_{cr} g^{0.5} H^{1.5} \quad (8)$$

in which C is a discharge coefficient, D_{cr} is the crest diameter, and H is the total head over the crest. The discharge equation for orifice control with the inlet of the shaft submerged is:

$$Q = C_o A_o \sqrt{2gH_o} \quad (9)$$

in which C_o is a discharge coefficient, A_o is the cross-sectional area at the vertical transition throat, and H_o is the total head at the throat section.

2. Submergence Limit

Camp and Howe 16/, Wagner 6/, White and McPherson 6/, Blaisdell 10/, Lazzari 18/, Bunt 24/, and Çatakılı 19/ experimentally determined the submergence limit, H/D_{cr} , at which the transition from weir to orifice flow occurs in circular sharp-crested weirs. The submergence limit was found to be affected by the approach velocity at the crest, by the pressure under the lower nappe of the flow, and by vortices. The submergence limit, H/D_{cr} , increases as the approach velocity decreases and as the pressure under the lower nappe decreases as shown in Figure 26. The submergence limit, H/D_{cr} , as found by the above mentioned investigators is as follows:

Wagner	0.225
White and McPherson	0.30
Blaisdell	0.235 - 0.245
Lazzari	0.25
Camp and Howe	0.25
Çatakılı	0.245
Çatakılı	0.35

Figure 26. Effect of Pressure Under Nappe and Approach Velocity on Submergence Limit of a Shaft-Spillway Inlet [After Catakli 19/]

Figure 27. Submergence Limit of Flow over a Sharp-Crested Circular Weir [After Wagner 6/ and Catakli 19/]

Wagner and Çatakılı showed that there exists a transition zone between weir and orifice control as shown in Figure 27.

Shaft spillways will not submerge at the same submergence limit, H/D_{cr} , since the transition from weir to orifice control is affected by the proportioning of the other geometric elements as was explained on Figure 6. Flow through 15 shaft spillways of Table A-1 of Appendix A were analyzed and their submergence limit determined as shown in Figure 28. Few spillways submerged at H/D_{cr} equal to 0.20 - 0.30, the rest submerged at H/D_{cr} less than 0.20 indicating the effect of the other geometric elements such as the shaft diameter, the throat diameter, or the deflector.

If the crest profile is steeper than of a lower nappe of flow over a sharp-crested circular weir, pressure fluctuations accompanied by vibrations and a sudden shift of control can occur as is shown in Figure 7a.

3. Air Demand

Air is entrained into a shaft spillway from the reservoir pool by the downward flowing water as shown in Figure 4a. Air can also be entrained at the vertical transition in case the vertical transition profile is shaped steeper than for an aerated lower nappe flow over a sharp-crested circular weir or at below a deflector inserted at the throat of the transition as shown in Figure 4b. The dimensionless parameter, Q_a/Q , where Q_a is the air discharge and Q is the water discharge, can be used in relation with other flow parameters to formulate the air demand.

a. From the Reservoir Pool. Few investigations have been made

Figure 28. Submergence Limit of Existing Shaft Spillways

to determine the amount of air entrainment by the water flow from the reservoir pool. The amount of air entrained by the Burnhope shaft spillway model 3/ is shown in Figure 29a, by the water flow through a 1-inch diameter sharp-ended pipe 41/ is shown in Figure 29b, by the water flow through a 1-inch diameter pipe with a trumpet-shaped entrance 5-inch in diameter 41/ is shown in Figure 29c, and by the water flow through 4-inch and 6-inch diameter shaft spillway models 78/ are shown in Figures 29d and 29e, respectively. No conclusive relation between the ratio of air discharge to water discharge, Q_a/Q , and flow parameters could be formulated. A similarity criterion for air entrainment into water flow does not exist at present 69/, though some studies are under way 79/. The above mentioned air demand ratios can only be used qualitatively in the absence of a similarity criterion. Air-discharge to water-discharge ratios, Q_a/Q , varied from over 100 per cent at low water flows with weir control to zero per cent with orifice control.

b. At the Vertical Transition. The air demand, Q_a , for flow over a sharp-crested weir was determined by Hickox 42/ and Obadia and Shieh 43/. Plots of the parameter Q_a/Q versus flow and geometric parameters are shown in Figure 30.

The maximum air demand ratio, Q_a/Q , for sharp-crested weir was found to be approximately 5 per cent. The U.S. Bureau of Reclamation 7/ measured the air demand through air vents at the vertical transition for Hearte Butte shaft spillway and found that the maximum air demand, Q_a/Q , was 5 per cent in the model and 20 per cent in the prototype (Figure 30d).

B. Transition from Short-Tube to Pipe Control

1. General

If the purpose of a dam is flood control, irrigation, or public or industrial water supply, where the discharge is to be limited in the river downstream from the dam, the shaft spillway is designed to operate unsubmerged at low discharges and to operate submerged at higher discharges. Submergence can be achieved by transition from weir to orifice control, as was discussed in Chapter III-A, or by transition from weir to short-tube control, as shown in Figures 5c and 6c. Of the ninety-six shaft spillways reviewed in Table A-3 of Appendix A, seventeen shaft spillways operated submerged at design capacity. Figure 31 shows the discharge curve of the Hearte Butte spillway in which the purpose of the dam was irrigation, flood control, and industrial water supply.

With short-tube control, the vertical shaft flows full of water and the flow control is at the bottom of the vertical shaft. Air entrainment from the pool surface ceases (Figure 29c) or is minimal if air is entrained through a vent at the throat (Figure 30d). The flow conditions in the horizontal conduit of either partly-full or pipe flow are influenced by the nature of the control at the bottom of the shaft. The discharge equation for short-tube control is:

$$Q = C_s A_s \sqrt{2gH_s} \quad (10)$$

in which C_s is a discharge coefficient, A_s is the cross-sectional area at the bottom of the vertical shaft, and H_s is the total head referenced to the bottom of the vertical shaft. The discharge equation for pipe control is:

Figure 31. Reservoir Elevation - Discharge Relation of Hearste Butte Vertical-Shaft Spillway

$$Q = A_c \sqrt{\frac{2gh_v}{K}} \quad (11)$$

in which A_c is the cross-sectional area of the horizontal conduit, h_v is the velocity head, $V^2/2g$, at the outlet portal, and K is a total loss coefficient. The pool-discharge relationships for short-tube and pipe controls are shown in Figures 5e and 6e. The nature of the flow control at the bottom of the vertical shaft is affected by the bend geometry, by any inserts placed at the vertical bend such as a deflector, and by air entrainment.

Figure 32 shows a typical flow condition with short-tube control. Dimensionless parameters are used to evaluate the results. The dimensionless geometric variables are the ratio of the mean radius of curvature to the difference between the outer and the inner radii of the bend, r/B , and the ratio of the deflector thickness to the horizontal dimension of the vertical shaft, t/B . The dimensionless parameters of the flow in the horizontal conduit are the ratio of the air discharge to the water discharge, Q_a/Q , the Froude number, F , defined by V/\sqrt{gd} in which V is the mean velocity and d is the mean depth of the water flow, and the ratio of the area of water flow to the area of the horizontal conduit, A/A_c . Froude number, the ratio of the water-flow area to the conduit area, and the ratio of the air discharge to the water discharge are determined throughout the water discharge range until incipient-sealing conditions.

2. Flow Conditions Prior to Sealing

Since any transition to pipe control occurs within the horizontal conduit and since sealing results from splashing and wave contact against

Figure 32. Definitive Sketch for Short-Tube Control Flow

the roof, an analysis of the flow conditions within the horizontal conduit prior to sealing is required in order to evaluate the experimentally determined incipient-sealing conditions.

a. Theory. The following theoretical analysis is to evaluate the ratio of water-flow area to conduit area, A/A_c , as a function of the Froude number, F , for various bends and deflectors. In problems of this type, the value of A/A_c is expected to be a function of F for low values of the Froude number and to be independent of the Froude number for high values.

The value of A/A_c in the range of low Froude numbers can be derived by referring to Figure 32a. The continuity equation between sections 1 and 2 is

$$V_1 (B-t) = V_2 d \quad (12)$$

Assuming uniform velocity distribution at sections 1 and 2, assuming constant air pressure over the water surface, and neglecting head losses, the total-head equation is

$$\frac{V_1^2}{2g} + \left(r + \frac{B}{2} \right) = \frac{V_2^2}{2g} + d \quad (13)$$

Eliminating V_1 , from Equation 13 by means of Equation 12 and solving for the Froude number, $F = V_2 / \sqrt{gD}$

$$F = \sqrt{\frac{2 \left(\frac{r/B + 1/2}{d/B} \right)^{-2}}{1 - \left(\frac{d/B}{1 - t/B} \right)^2}} \quad (14)$$

Inasmuch as $d/B = A/A_c$, Equation 14 is the desired function relating A/A_c and F for the range of low Froude numbers.

The values of A/A_c in the range of high Froude numbers can be approximated from an irrotational-flow two-dimensional free-jet solution for a 90-degree miter bend obtained by Ambrose 80/. The flow depth in the horizontal conduit, d/B , depends on the vertical distance between the line of separation of the flow at the upstream end of the bend and the floor of the horizontal conduit, $r + \frac{B}{2}$, and on the horizontal dimension of the vertical shaft, $B-t$. Values of d/B from Ambrose's solution are tabulated below for values of r/B and t/B used in this experimental program.

$\frac{r}{B}$	$\frac{t}{B}$	$\frac{d}{B} = \frac{A}{A_c}$
0.5	0	0.52
	1/64	0.52
	1/16	0.52
	1/8	0.52
1.5	0	0.81
	1/64	0.81
	1/16	0.78
	1/8	0.75
2.5	0	0.94
	1/64	0.92
	1/16	0.89
	1/8	0.85

b. Experimental Results. Experimental results and theoretical functions are shown in Figures 33-35 inclusive for flow conditions in the horizontal conduit. The solid lines in the figures are the theoretical functions of Equation 14 and of Ambrose. The theoretical functions are seen to be reasonable representations of the measured values except for the two bends, $r/B = 1.5$ and $r/B = 2.5$, without a deflector, $t/B = 0$, shown in Figures 34 and 35. The lack of agreement with the theoretical functions without a deflector is because in the theory leading to Equation 14 and in using Ambrose's solution, the line of separation was assumed to occur at the beginning of the bend as shown in Figure 36 whereas in the two exceptions the line of separation shifted to a lower elevation as shown in Figure 37.

Experimental results and theoretical functions are shown in Figures 38-43 inclusive for flow conditions within the horizontal conduit for various values of air concentration, Q_a/Q . The results with aerated flow are similar to those of non-aerated flow except for the two bends, $r/B = 1.5$ and $r/B = 2.5$, without a deflector, $t/B = 0$, shown in Figures 38 and 39. The lack of agreement is because the air separated from the water at the inner wall of the bend, due to the centrifugal force acting on the bubbly mixture, thus fixing the control at a section along the inner bend wall. Since the flow depth, d , was measured on the water manometer which determined the equivalent aerated-flow depth and since the mean velocity of aerated flow is larger than of a non-aerated flow 60/, the value of d and hence of A/A_c was smaller for aerated flow. The air bubbles passed through the bend and flowed into the horizontal conduit in an ascending trajectory (Figure 44) creating

a frothy surface as the bubbles escaped from the water surface. Water droplets splashed against the roof and the maximum water depth (or spray) was more than the corresponding non-aerated flow.

3. Flow Conditions at Incipient Sealing

Conditions at incipient sealing are the upper limit for the flow in the horizontal conduit before a shift from short-tube to pipe control occurs. Figures 36, 37, 44, and 45 show the flow conditions in the horizontal conduit at incipient sealing. Figure 46 shows typical piezometric-head lines along the conduit.

Before discussing the flow conditions at incipient sealing that eventually lead to sealing of the conduit, the phenomena that could not have caused sealing are reviewed.

The first possibility is the hydraulic jump. A hydraulic jump can occur in a rectangular conduit if there exists a subcritical conjugate depth, d_2 , downstream of the supercritical flow of depth d_1 , that satisfies the equation

$$\frac{d_2}{d_1} = \frac{1}{2} \left(\sqrt{1 + 8F_1^2} - 1 \right) \quad (15)$$

For the bend of $r/B = 0.5$ sealing occurred at a Froude number $F = 8.0$ (Figure 33) which requires a conjugate depth, d_2 , equal to $11 d_1$. A conjugate depth, d_2 , was not available since the flow discharged freely at the outlet.

The second possibility is that the backwater curve depth increases. For supercritical flows ($F > 1$) on mild slopes the backwater curve is classified M-3. Backwater profile computations, with the point

(a) $r/B = 1.5$ and $t/B = 1/4$

Figure 45. Flow Conditions Downstream of the Deflector, $t/B = 1/4$, at the roof of the Conduit at Incipient Sealing (Short-Tube Control, and $Q_a/Q = 0.0$)

Figure 46. Typical Piezometric-Head Elevations Along Horizontal Conduit (Short-Tube Control)

of separation fixed at the deflector at the crown of the bend, show that the flow depth at the outlet portal decreases as the discharge increases. Sealing, therefore, due to a backwater profile touching the roof of the conduit was not possible.

An explanation of the flow conditions leading to and at incipient sealing follows. As the water discharge was increased, the free-surface-supercritical flow, due to the shear stress developed at the interface between the water and the air, dragged out the layer of air adjacent to the water surface as shown in Figure 47a. The interfacial shear stress depends on the relative velocity of the water and air flow and on the interfacial disturbances 81, 82, 83/. The interfacial disturbances are due to the nature of the supercritical flow and are due to the water droplets breaking away from the water surface. Vedernikov 84/ and Rouse 85/ found that the water surface in supercritical flow is unstable and wavy. Clumps and droplets of water break away from the water surface when the transverse velocity of water and the turbulence are sufficiently strong at the interface or when the air bubbles in an aerated flow escape from the water surface forming a froth. Figures 36,37,44, and 45 show the water droplets over the turbulent water-air interface. From the equation of continuity, an equal amount of air has to enter from the outlet portal to replenish the amount of the outflowing air. A circulatory air current was thus established as shown in Figure 47a. Sketches of the velocity distribution and the shear stress distribution in the air layer are shown in Figure 47b. The drag of the water on the air established a negative pressure gradient inside the conduit. The pressure results are shown in Figure 48. The pressure decreased with

Figure 47. The Circulatory Air Current in the Conduit

Figure 48. Air Pressure at the Roof of the Conduit

the increase of the water velocity and of the interfacial disturbances. The velocity of the inflowing air depends on the interfacial shear stress and on the area of the air flow. With the increase of the water velocity and/or aeration of the flow, water droplets splashed at the roof of the conduit, more air was dragged out, the area of the inflowing air flow became smaller, and subsequently the velocity of the inflowing air increased. If the velocity of the water droplets in the direction of the water flow is greater than the velocity of the inflowing air, the water droplets fall back to the water surface without choking the conduit as shown in Figure 49a. At incipient sealing, the velocity of the inflowing air becomes larger than the velocity of the droplets, hence the water droplets deflect into the direction of the inflowing air as shown in Figure 49b. The water droplets choke the air layer above the water surface and thus seal the conduit. Appendix B-1 shows computations of the inflowing air velocity, based on the pressure at the roof of the conduit, as compared to the water velocity at incipient sealing. Qualitative runs were made with the air vents open at the upstream end of the conduit. Incipient sealing was delayed since the air entering the conduit from the vents substituted for the need of the inflow of air from the outlet portal, thus the air velocity profile changed to flow in the same direction as the water flow as shown in Figure 49c. With aerated flow, the increased spray caused a decrease of the space area and an increase of the velocity of the inflowing air which eventually hastened sealing.

Figure 50 shows the relation between the ratio of water-flow area to conduit area and the Froude number for all the bends and deflectors

Figure 49. Water Droplets Path for Various Air Velocity Distributions

Figure 50. Percent Flow Area Versus Froude Number at Incipient Sealing (Short-Tube Control)

tested at incipient sealing. The ordinates for the bend of $r/B = 2.5$, with $t/B = 0.0$, were low because the control shifted quickly to the downstream end of the bend and a closer measurement to incipient sealing could not be made. The ordinates for the bends $r/B = 1.5$ and 2.5 with deflectors show some scatter which was due to an increased disturbance at the edge of the deflector or at the joints of the model. At higher Froude numbers more air space above the water surface is needed to accommodate the splash of the water droplets and to provide air-flow area large enough to keep the velocity of the inflowing air less than the velocity of the water droplets. With some aeration the water splash increased and incipient sealing was at lower Froude numbers than the corresponding non-aerated flow. With additional ventilation from the air vents at the roof of the conduit, incipient sealing was at higher Froude numbers than the corresponding non-ventilated flow.

C. Transition From Weir to Pipe Control

1. General

If the purpose of the shaft spillway is to pass the excess flood water without overtopping the dam, the spillway is designed to discharge freely with weir control throughout the discharge range as shown in Figure 5a. Of the ninety-six shaft spillways reviewed in Table A-3 of Appendix A, thirty-one shaft spillways are known to have operated with weir control at design capacity.

With weir control, an air-water mixture flows in the vertical shaft and in the horizontal conduit. The discharge equation for weir control is:

$$Q = C D_{cr} g^{0.5} H^{1.5} \quad (8)$$

in which C is a discharge coefficient, D_{cr} is the diameter at the inlet crest, and H is the total head over the inlet crest. The discharge equation for pipe control is:

$$Q = A_c \sqrt{\frac{2gh_v}{K}} \quad (11)$$

A typical discharge-rating curve, that of Davis Bridge shaft spillway, is shown in Figure 51.

Air is entrained freely from the atmosphere at the pool surface. Figure 29 shows the variation of air concentration into the water flow throughout the weir control range as were measured in models. The air concentrations ranged from 100 per cent at low discharges to zero per cent at the transition to orifice control.

This experimental investigation was to study systematically the effect of air concentration, Q_a/Q , bend curvature, r/B , and the ratio of the deflector thickness to the horizontal dimension of the shaft, t/B , on sealing of the horizontal conduit. Weir control conditions were simulated by letting the water flow eject from a multiple-tube outlet (Figure 14) into the vertical shaft and then through the horizontal conduit. Various amounts of air were entrained into the water flow, at a section just below the multiple-tube outlet, to produce the air-water mixture. Sealing of the conduit is defined by the condition when any section of the conduit is under pressure. Sealing was determined by taking piezometric-head measurements along the floor of the conduit and by pressure measurements at the roof of the conduit. Dimension-

Figure 51. Discharge Rating Curve and Flow Characteristics in Conduit for Davis Bridge Vertical-
 Shaft Spillway

less parameters are used to describe the characteristics of the flow in the horizontal conduit. The dimensionless variables are the bend curvature, r/B , and the ratio of the deflector thickness to the horizontal dimension of the shaft, t/B . The dimensionless parameter of the flow in the horizontal conduit are the ratio of the air discharge to the water discharge, Q_a/Q , the Froude number, F , and the ratio of the area of the water flow to the area of the conduit, A/A_c . Froude number, the ratio of the area of the water flow to the area of the conduit, and the ratio of the air discharge to the water discharge were determined throughout the discharge range until incipient sealing.

2. Flow Conditions Prior to Sealing

Since transition to pipe control occurs within the horizontal conduit and since sealing results from wave contact against the roof, an analysis of the flow conditions within the horizontal conduit prior to sealing is required in order to evaluate the experimentally determined incipient-sealing conditions.

a. Theory. The wave height in the free-surface flow in the horizontal conduit depends on the Froude number. Considering a vertical shaft spillway with a total head, H_T , from the pool surface to the flow surface in the conduit and assuming the head losses, h_L , to be approximately equal to 15 per cent of the total head, then the velocity of the flow in the conduit can be written as

$$V = \sqrt{2g (H_T - h_L)} \quad (16)$$

Froude number can be related to the ratio of water-flow area to conduit area, A/A_c , as

$$F = \frac{V}{\sqrt{g \frac{d}{D_c} D_c}} = \sqrt{\frac{2}{d/D_c} \frac{H_T - h_L}{D_c}} \quad (17)$$

in which d is the flow depth in the conduit and D_c is the conduit diameter. Inasmuch as A/A_c is related to d/D_c , Figure 52 shows the relation between F and A/A_c according to Equation 17 for the maximum and minimum H_T of existing spillways. Experimental results from model tests of existing shaft spillways are also shown in Figure 52.

b. Experimental Results. The experimental results are shown in Figures 53-57, inclusive for flow conditions in the horizontal conduit. The experimental results are in close agreement with Equation 17 and the existing shaft spillways. The variation of the air concentration throughout the discharge range is also comparable to actual conditions where air is entrained from the pool surface (Figure 29). The surface of the air-water mixture flow in the horizontal conduit was wavy and frothy as shown in Figure 58. The wavy flow surface in the horizontal conduit is caused by the impact of the falling air-water mixture on the floor of the conduit. The bend of $r/B = 0.5$ induced the largest waves and the bend of $r/B = 2.5$ induced the smallest waves. Air bubbles ejecting from the water surface formed a frothy surface with a layer of water droplets over the main mass of water flow. With more air entrainment into the water flow, the spray of droplets and the layer of froth increased, the amount of air ejecting as the bubbles of air escaped through the water surface increased, and the layer of froth moved with the direction of the water flow as shown in Figure 59. As

Figure 58. Flow Conditions at the Bend and in the Horizontal Conduit Prior to Sealing (Weir Control)

Figure 59. Effect of Froth on Sealing

long as the layer of froth moves with the velocity of the water flow no sealing occurs.

3. Flow Conditions at Incipient Sealing

Figure 60 shows typical piezometric-head lines along the floor of the conduit at incipient sealing. Figures 61 and 62 show the experimental results. Sealing occurs when the wavy water surface touches the roof. Figure 61 shows that with increasing air concentration, Q_a/Q , less area above the water-flow area is needed at incipient sealing because the air ejecting from the water surface helps to move the water spray with the direction of the water flow and forms a frothy layer over the flow surface that acts as a buffer layer between the wavy flow surface and the roof of the conduit. At the high air concentrations, transition to pipe flow was smooth, since the flow in the conduit was bubble flow with no distinct air-water interface, in contrast to conditions at low air concentrations where the transition was sudden and violent. The wave height at the flow surface is directly related to the Froude number. The larger the Froude number the greater the waves. Figure 62 shows that at larger Froude number, greater concentrations of air, Q_a/Q , are needed to counter the effect of the waves and to form the frothy surface to act as a buffer layer between the flow surface and the roof of the conduit. A deflector at the roof of the upstream end of the conduit suppressed the wave action and thus delayed sealing. With small air concentrations, a deflector at the crown of the bend deflected the flow away from the roof of the conduit and helped delay sealing. With large air concentrations the conduit was full of bubble flow and the deflector at the crown of the bend had

Figure 60. Typical Piezometric-Head Elevations Along Conduit (Weir Control)

Figure 61. Percent Flow Area Versus Air Concentrations at Incipient Sealing (Weir Control)

Figure 62. Froude Number Versus Air Concentrations at Incipient Sealing (Weir Control)

no effect. Qualitative runs were made with the air vents at the roof of the conduit open. With small air concentrations, sealing was delayed because air entering the conduit from the vent substituted for the need of air from the outlet portal and kept the velocity of the inflowing air less than that of the water droplets splashing from the water surface (Figure 49c).

Figure 63 shows the relation between the ratio of the water-flow area to the conduit area and the Froude number. With larger Froude numbers more area is needed above that of the water-flow area to accommodate the waves and the bulking of the flow. With increasing air concentrations less extra area is needed because the frothy surface counters the effect of the waves.

D. Summary

With weir control, transition to orifice control occurs at a ratio of head over the inlet crest to diameter at the crest, H/D_{cr} , approximately equal to 0.25 as shown in Figure 27. The size of the throat and of the vertical shaft also affect the transition to orifice or to short-tube control.

With short-tube control, transition to pipe control depends on the Froude number, F , of the flow in the conduit. With larger Froude numbers, more area is needed above the water-flow area, as shown in Figure 50, to have the velocity of the inflowing air from the outlet portal less than the velocity of the splashing water droplets. The water-flow area depends on the height of the control section at the upstream end of the bend above the floor of the conduit, $r + \frac{B}{2}$, and

Figure 63. Percent Flow Area Versus Froude Number at Incipient-Sealing (Weir Control)

on the horizontal dimension of the vertical shaft, $B-t$. Conduits downstream of bends with small ratios of r/B or of bends with a deflector flow with a smaller flow area and thus can pass more water discharge with partly-full flow than the conduits downstream of bends with large ratios of r/B or of bends with no deflectors. Air entrainment into the water flow hastens the transition to pipe control and ventilating of the conduit delays the transition.

With weir control, transition to pipe control depends on the Froude number, F , of the flow in the conduit. With larger Froude numbers, more area is needed above that of the water-flow area to accommodate the waves and the bulking of the flow as shown in Figure 63. Bends of small ratios of r/B cause more wave action and hastens the transition. A deflector at the roof of the conduit suppresses the waves and delays the transition. Air entrainment into the water flow dampen the wave action by forming a frothy surface and delays the transition to pipe control. At high air concentrations the transition to pipe flow is smooth in contrast to the conditions at low air concentrations where the transition to pipe flow is sudden and violent.

CHAPTER V

DISCUSSION

In this chapter a general discussion on shaft spillways is presented.

A. Vertical versus Inclined Shaft Spillway

The type of shaft selected depends on topographic, geologic, economic, and hydraulic considerations.

With the horizontal leg of the spillway embedded into an earth dam, a vertical shaft is used. At narrow rocky sites, topographic suitability at the inlet or the location of the power house or other installations affects the choice between a vertical or inclined shaft.

Geologically, a shaft is preferably excavated at right angle to the bedding planes of the rock to minimize excavation overbreak of the rock.

The choice between an inclined or vertical shaft is also based on economic studies. A vertical or inclined shaft spillway is excavated by first drilling a smaller shaft then enlarging the shaft by extra excavation dumping the excavated material through the already drilled core of the shaft. An inclined shaft excavated at an angle of inclination larger than the angle of repose of rock such as at an angle of 50 degrees so that the rocks can be rolled along the shaft by gravity becomes as easy and as cheap to excavate as a vertical shaft. However, the length of an inclined shaft is shorter than that of a corresponding vertical

shaft and the portion of the horizontal conduit, subsequently the amount of excavation from an inclined shaft is less which makes the inclined shaft in general cheaper than the vertical shaft.

Hydraulically, a vertical shaft with a 90-degree-angled bend generates more waves onto the free-surface flow in the horizontal conduit than an inclined shaft with a 130-degree-angled bend. Therefore, an inclined shaft spillway is preferable since at a flow with the same Froude number the inclined shaft spillway requires less extra area above the water-flow area. Also, an inclined shaft can drag air along the water surface from the atmosphere at the upstream end of the shaft in contrast to a vertical shaft where the vertical inlet is full of water and air has to enter the conduit from the outlet portal causing sealing of the conduit.

As a conclusion, the inclined shaft is preferred to the vertical shaft.

B. Free versus Submerged Inlet

The purpose of a dam determines the discharge characteristic of a spillway. For the purpose of passing the excess flood water without overtopping the dam, a free discharge over the crest with weir control is necessary. For the purpose of flood control where the discharge is to be limited in the river downstream from the dam, a submerged inlet is required with either orifice or short-tube control.

C. Partly-full versus Full Conduit

Since transition to pipe flow or sealing causes undesirable vibrations of the structure and fluctuations of the flow discharge, the

conduit should flow partly full throughout the discharge range. However, if the purpose of the dam is flood control with pipe flow as the preferred flow control, then transition to pipe control should be achieved at a low discharge 40/. With the tailwater elevation higher than the outlet elevation (submerged outlet), air entrainment should be kept at a minimum to avoid the possibilities of blow out of air pockets at the outlet 86/.

D. Conduit-Size Determination

1. Discussion of Results

Figure 50 shows the conditions for the upper limit of partly-full flow in a square horizontal conduit with short-tube control and Figure 63 shows the conditions with weir control. The upper limit of partly-full flow depends on the turbulence of the water flow that causes water droplets to break away from the surface, on the waves over the flow surface, and on the velocity of the inflowing air from the outlet portal. With higher water velocities and greater waves over the flow surface, more space above the water-flow area is needed to accommodate the waves and to increase the inflowing air-flow area to keep the inflowing air velocity smaller than that of the splashing water droplets. A wavy-surface flow demands more extra space above the water-flow area than a corresponding smooth-surface flow as can be seen by comparing Figures 50 and 63.

Factors affecting the turbulence in the flow or the waves affect the upper limit for partly-full flow. With short-tube control where the flow surface is smooth, roughness of the concrete surface or irregularities at the joints cause increased turbulence in the flow that results

in more water droplets splashing against the roof. The inflowing air from the outlet portal can hasten sealing of the conduit. Ventilation from the upstream end of the conduit decreases the air demand from the outlet portal reducing the velocity of the inflowing air thereby delaying sealing. With weir control where the flow surface is wavy, highly aerated flow forms a frothy surface that counters the wave action. The air that ejects from the flow forms an air current in the direction of the water flow thereby reducing the air demand from the outlet portal.

Figures 50 and 63 for square conduits are reasonable to use with circular conduits. The phenomenon of sealing with the water droplets breaking away from the water surface and air flowing into the conduit from the outlet portal or with the waves touching the roof is the same in both the circular and the square conduit. With flow in circular conduits more wave action and surface disturbances are expected because of the tendency that the flow turn along the arched roof onto the main stream of flow. Therefore, in a circular conduit it is reasonable to allocate more space area above the water surface than in a rectangular conduit. If the values of A/A_c for the rectangular conduit of this investigation are applied to circular conduits somewhat more space is required to compensate for the additional wave action and surface disturbances.

With a flow deflector at the outlet portal, there exists the possibility of a hysteresis phenomenon where a hydraulic jump can occur in the conduit as the discharge is decreased thus sealing the conduit as was demonstrated by Abecasis and Quintela 87/.

Since similarity criteria for turbulence and air demand are

inadequately established, these experimental results should be used only for initial selection of near optimum designs.

2. Design Criterion

Sealing of the horizontal conduit depends on the Froude number of the flow. Figure 50 shows the relation of Froude number, F , to A/A_c for short-tube control. The required ratio of A/A_c can be achieved by the proper choice of bend and deflector combination as was demonstrated experimentally and solved for analytically by Ambrose 80/. The existing shaft spillways of Table A-3 of Appendix A with circular conduit are in fair agreement with the suggested limit (Figure 50) as shown in Figure 64. Figure 63 shows the experimental results with weir control and Figure 65 shows the same information for existing spillways. Inclined shaft spillways generate less wave action and are ventilated from the inlet. The upper limit of partly-full flow conditions for an inclined shaft approach those for a vertical shaft with short-tube control. The criterion of the Portugese National Civil Engineering Laboratory (L.N.E.C.) 13/ of allowing 86 per cent water-flow area and of the U.S. Bureau of Reclamation (U.S.B.R.) 12/ of allowing 75 per cent water-flow area are also in agreement with the suggested criterion since the L.N.E.C. and the U.S.B.R. spillways operated at Froude numbers not exceeding the limit of Figures 50. Since the L.N.E.C. and the U.S.B.R. limits of flow area in the conduit are specific limits found from experience with specific model studies without differentiating between weir control and short-tube control, these limits can not be general.

E. Bend Curvature

With short-tube control, the bend and the deflector determine

Figure 64. Comparison of Existing Shaft Spillways with Suggested Criterion (Short-Tube Control)

Figure 65. Comparison of Existing Shaft Spillways with Suggested Criterion (Weir Control)

the depth of flow in the horizontal conduit. The depth of flow depends on the vertical distance between the line of flow separation at the upstream end of the bend and the floor of the conduit, $r + \frac{D_c}{2}$, and on the diameter of the vertical shaft, D_t . From Ambrose's analysis 80/, a bend of small ratio of r/D_b acquires a smaller flow area than a bend of large ratio of r/D_b , consequently would seal at a higher Froude number.

With weir control, a bend of small ratio of r/D_b generates larger waves than a bend of large ratio of r/D_b . Accordingly, for a higher Froude number flow a vertical bend with r/D_b ratio larger than 2.0 is recommended. Figure 66 shows the relation of Froude number to bend curvature, r/D_b , for the existing shaft spillways of Table A-3 of Appendix A. Figure 66 shows the confusion among the designers in choosing a bend curvature. For inclined shaft spillways the U.S. Bureau of Reclamation suggests a bend curvature of at least $r/D_b = 8.0$ 88/.

F. Air Demand

Air demand of a shaft spillway is that amount of air dragged out with the outflowing water flow which has to be replenished either from the outlet portal, from an air vent in the conduit, or from the air entrained into the flow at the pool surface. An inflowing air current from the outlet portal in an opposite direction to the water flow causes sealing of the conduit since it deflects the splashing water droplets which choke the space above the water flow. After the air-velocity profile is established the length of the conduit has no effect on the discharge of the inflowing air since the discharge is the product of the velocity times the flow area.

Formulation of air demand in relation to flow parameters such as

Figure 66. Relation of Bend Curvature to Froude Number for Existing Shaft Spillways

Froude number could not be achieved in this investigation because only pressure measurements were made. However, Campbell and Guyton 51/ attempted to formulate the air demand theoretically but were unsuccessful because they could not estimate the value of the drag force acting on the air flow. Instead, Campbell and Guyton measured the air demand through an air vent in gated outlet works and related it to Froude number minus one for conditions prior to sealing. Ghetti and Di Silvio 56/ tried to determine the total air demand from the outlet portal and from an air vent in the conduit and to study the effect of the air vent size on the air movement in outlet works. To delay sealing, the air layer above the water surface should flow in the same direction of the water flow.

The air entrained into the flow from the pool surface serves to form a frothy surface in the horizontal conduit and to aerate the conduit. Although the air segregates from the water flow along the length of the conduit, the air ejecting from the water surface eventually forms an air current above the water surface which helps delay sealing. Aeration of the flow cushions the impact of the water on the floor of the vertical bend 7/, reduces cavitation damage 39/, leads to greater and more efficient dissipation of energy in the stilling basin downstream of the horizontal conduit 47/, and increases the total head losses in the spillway as compared to a non-aerated flow 89/. However, with short-tube control, air entrainment into the flow hastens sealing in contrast to conditions with weir control.

Special measures should be taken to entrain air since only small amounts of air are entrained from the pool surface by the falling water

as shown in Figure 29 and at an air vent at the throat of a shaft as shown in Figure 30 at about incipient-sealing conditions. One measure is to build the crest profile in a stepped shape as that of Lady Bower shaft spillway 5/ and as is shown in Figure 67. The prototype behavior of Lady Bower shaft spillway was described as:

It has been noted that when the spillway is discharging heavily the cascade of broken water falling down the shaft acts as an air pump and produces an air current charged with spray, which discharges out the lower end of the tunnel in considerable volume. Contrary to expectations, the discharge is slightly greater for a given head with the stepped morning-glory than with a smooth one. The spillways have proved a highly efficient method of discharging overflow water from the reservoir and they are entirely reliable for that purpose.

G. Design Examples

The following design examples are considered to illustrate the use of the suggested design criteria of Figure 50 and Figure 63 in choosing an initial near optimum conduit size and a suitable bend. The flow conditions of Hearte Butte shaft spillway, as shown in Figure 31, are chosen for illustration. The purpose of the dam was flood control. The maximum discharge with weir control is 3000 cfs and the maximum discharge with submerged short-tube control is 5600 cfs.

1. Design for Short-tube Control

Using a constant-diameter conduit of the same dimension as of the vertical shaft, $D_c = 11.0$ ft. The conduit area becomes $A_c = \pi D_c^2 / 4 = 154 \text{ ft}^2$. Assume $A/A_c = 0.75$, then $A = 116 \text{ ft}^2$, $V = 48$ fps, hydraulic depth = 7.1 ft, and $F = 3.18$. Figure 50 shows that the flow with $F = 3.18$ and $A/A_c = 0.75$ is a little less than at incipient-sealing conditions. $A/A_c = 0.75$ corresponds to $d/D_c = 0.70$. From Ambrose analysis

Figure 67. Stepped-Crest Profile

80/ for $d/D_c = 0.70$ the value of $(r + D/2)/D$ is equal to 1.5 which corresponds to a bend curvature $r/D_b = 2.0$ similar to the actual design.

2. Design for Weir Control

A check for partly-full flow conditions with weir control is necessary to assure that the conduit will not seal. At $Q = 3000$ cfs the height of the pool surface is 6 ft above the spillway crest.

For the shaft; $A = 145 \text{ ft}^2$, $V = 19.5 \text{ fps}$, and $V^2/2g = 5.9 \text{ ft}$. Assume entrance loss coefficient $K_{\text{ent.}} = 0.1$, bend loss coefficient $K_b = 0.1$, and Mannings' roughness coefficient $n = 0.018$. Friction loss coefficient $K_f = \frac{29.1 n^2 L}{R^{4/3}}$.

$$K_f = \frac{29.1 \times (0.018)^2 \times 31}{2.92} = 0.1$$

Total loss coefficient for the shaft portion, $K = 0.3$ and $h_L = 1.77 \text{ ft}$.

For the conduit portion; assume $d/D_c = 0.50$, then $A/A_c = 0.50$, $A = 77 \text{ ft}^2$, $V = 39 \text{ fps}$, and $V^2/2g = 23.7 \text{ ft}$. Friction loss coefficient $K_f = \frac{29.1 n^2 L}{R^{4/3}} = \frac{29.1 \times (0.018)^2 \times 625}{3.82} = 1.55$ and $h_L = 36.6 \text{ ft}$.

From energy considerations

$$d + h_L + \frac{V^2}{2g} = H_c + H$$

$$5.5 + 36.6 + 1.77 + 23.7 \cong 61.7 + 6$$

Therefore the hydraulic depth = 4.3 ft and $F = 3.3$. Figure 63 shows that flow conditions with $F = 3.3$ and $A/A_c = 0.50$ are well below incipi-

ent-sealing conditions.

It is a good design practice to insert a deflector at the crown of the bend so as to fix the flow control at the bend in case the flow shifts to short-tube control. The deflector helps keep the horizontal conduit flowing partly-full.

H. Summary

The results of this study are not aimed at eliminating the need for model studies of shaft spillways but rather to enable the designer to make better initial designs. Appreciable cost reductions can be made on shaft-spillway model construction by initial selection of near optimum designs because overly conservative designs add to construction cost. Unsafe designs which are detected during model tests require additional time and costs for revised design and model tests. For small spillways, where model studies are too costly, the experimental results can be used for safe near-optimum designs.

CHAPTER VI

CONCLUSIONS

This investigation has clearly demonstrated the role of the bend curvature, deflector, and air concentration on the phenomenon of sealing or transition to pipe control in the horizontal leg of a vertical-shaft spillway. The following conclusions can be made:

First, sealing of the horizontal conduit depends on the Froude number of the flow. To maintain partly-full flow in the horizontal conduit more space above the water-flow area is needed with an increase of Froude number. Additional extra space is needed with wavy-surface flow or with aerated flow. With short-tube control, the bend curvature, r/D_b , and the deflector thickness determine the maximum water-flow area in the conduit.

Second, with short-tube control, bends of small ratios of r/D_b pass more discharge at partly-full flow in the conduit than bends of large ratios of r/D_b because the flow area in the conduit is smaller. With weir control, bends of smaller ratios of r/D_b generate more waves.

Third, with short-tube control, aeration of the flow bulks the flow and hastens sealing. With weir control, aeration of the flow forms a frothy surface that dampen the waves. Ventilation of the conduit from the outlet portal causes an inflowing air current into the conduit in the opposite direction of the water flow which leads to sealing of the conduit. Ventilation from the upstream end of the conduit causes the

air current to flow with the direction of the water flow and delays sealing.

CHAPTER VII

RECOMMENDATIONS

In this investigation, the air demand from the outlet portal could not be measured or formulated nor could the air concentration in the flow be scaled to the prototype. The following recommendations are suggested:

First, a study of the air demand from the outlet portal and the effect of the air vent size at the upstream end of the conduit on the air movement in the space above the water area is recommended.

Second, a study for a similarity criterion for air entrainment in water flow is needed.

TABLE A-1 (Concluded)
DATA ON EXISTING SHAFT SPILLWAYS

References are given in REFERENCES of TABLE A-1 in APPENDIX-A
* At the outlet the diameter becomes 31 ft. horse shoe section
** Horse-shoe section
† Polygonal section
†† Elliptic Section

Symbols

H_c Difference of elevation between inlet crest and outlet invert, ft.
 Q Design discharge of spillway, cfs.
 H Head over inlet crest at design discharge flow, ft.
 D_{cr} Diameter of inlet crest, ft.
 r Radius of the bend measured till centerline of bend section, ft.
 D_b Diameter of the bend, ft.
 D_c Diameter of the circular horizontal conduit, ft.

TABLE A-2
STRUCTURAL AND OPERATIONAL CHARACTERISTICS

APPENDIX B

COMPUTATIONS

	Page
B-1 Air Discharge from the Outlet Portal	145

APPENDIX B-1

AIR DISCHARGE FROM THE OUTLET PORTAL

A simplified velocity distribution of the air layer above the water surface is considered as shown by the dashed line in Figure B-1. The discharge of the air and the velocity of the inflowing air can be computed, using the pressure data, as follows:

1. The inflowing air discharge equals the outflowing air discharge.

$$Q_a \text{ in} = Q_a \text{ out}$$

or

$$V_a \text{ in} (B-d-y) B = \frac{V_a \text{ out } y \cdot B}{2} \quad (B1)$$

in which $V_a \text{ out}$, B , and d are known. Assume $V_a \text{ out} = V \text{ water}$. The values $V_a \text{ in}$ and y are unknown.

2. Assume a value for y and compute $Q_a \text{ out}$.
3. Compute $V_a \text{ in}$ from Equation B1.
4. Compute the equivalent diameter of the inflowing air layer section.

$$D_e = 4 \frac{A_a}{P} \quad (B2)$$

in which: A_a = cross-sectional area of the inflowing air layer
 P = wetted perimeter at an inflowing air layer section

5. Compute Reynolds number for the inflowing air.

$$R_e = \frac{V_a \text{ in } D_e}{\nu}$$

6. Find Darcy-Weisbach friction coefficient, f , from Moody-diagram.

7. Compute friction loss coefficient, K_f ,

$$K_f = \frac{fL}{D_e}$$

in which L is the length of conduit.

8. Compute total loss coefficient, K .

$$K = K_f + K_{\text{entrance}} + K_v$$

in which: K_{entrance} = entrance loss coefficient = 0.5

K_v = velocity head coefficient = 1.0

9. Compute $V_a \text{ in}$ from,

$$V_a \text{ in} = \sqrt{\frac{2g p_a}{K}} \quad (B3)$$

in which: p_a = measured pressure at roof of conduit

10. Check if $V_a \text{ in}$ as found in steps 3 and 9 are equal. If not, then assume another value for y in step 2 and repeat steps 3 to 9, inclusive.

11. The maximum velocity of the inflowing air is 1.5 times the average velocity.

The results of the air discharge and of the air velocity are shown in Table B-1.

VITA

Yusuf G. Mussalli was born in Aleppo, Syria on February 2, 1939. He attended Aleppo College, an American missionary school, and graduated in June 1957. He graduated from Robert College, the American College of Istanbul, with a Bachelor of Science in Civil Engineering in July 1960. He worked with the Euphrates Project Authority in Syria from September 1960 to February 1963 and attended a seminar on irrigation and drainage in the summer of 1961 organized by the U.N. Food and Agriculture Organization in the Soviet Union. In February 1963 he joined the Middle East Technical University, Ankara, Turkey and graduated in December 1964 with a Master of Science in Civil Engineering. He worked with the Delft Hydraulics Laboratory, the Netherlands, from January 1965 to September 1965 as a civil engineer. He was placed at the Georgia Institute of Technology by the American Friends of the Middle East where he attended the Graduate Division from September 1965 to the present. He was awarded a Master of Science in Civil Engineering in June 1967. While at the Georgia Institute of Technology he was employed by the School of Civil Engineering as a graduate research assistant. During the summer of 1967 he worked for the U.S. Army Corps of Engineers, Sacramento, California as a hydraulic engineer.

At Georgia Tech, Mr. Mussalli was chosen as an Outstanding Middle Eastern Student in the U.S.A. in 1967 and as the Outstanding International Student at Georgia Tech in 1969. He was the president of the Organization of Arab Students at Georgia Tech, the vice president of the International

Student Organization in 1967, the vice president of the Episcopal Church on Campus in 1968. He is a member of the American Friends of the Middle East, an associate member of the American Society of Civil Engineers, a member of Chi Epsilon honorary civil engineering fraternity, a member of Sigma Xi research society, a member of the International Association for Hydraulic Research, and a member of the Water Pollution Control Federation.

He is single.
